ABSTRACT

Gravitational waves emitted by chirping supermassive black hole binaries could in principle be used to obtain very accurate distance determinations. Provided they have an electromagnetic counterpart from which the redshift can be determined, these standard sirens could be used to build a high redshift Hubble diagram. Errors in the distance measurements will most likely be dominated by gravitational lensing. We show that the (de)magnification due to inhomogeneous foreground matter will increase the scatter in the measured distances by a factor ~ 10 . We propose to use optical and IR data of the foreground galaxies to minimize the degradation from weak lensing. We find that the net effect of correcting the estimated distances for lensing is comparable to increasing the sample size by a factor of three when using the data to constrain cosmological parameters.

Subject headings: cosmological parameters — gravitational lensing — gravitational waves

1. INTRODUCTION

The distance–redshift relation for electromagnetic standard candles, such as Type Ia supernovae, has been crucial to our understanding of the energy content of the Universe. With the advent of laser interferometric gravitational wave detectors, such as LIGO¹ and the

¹<http://www.ligo.caltech.edu/>

planned space mission LISA², new windows to the Universe will be opened. Binary systems with shrinking orbits, emitting gravitational waves just before coalescence, are expected to be standard sirens, the gravitational wave analogy of electromagnetic standard candles (Schutz 1986, 2002). Since the frequency of the gravitational waves rises when the orbit changes, these systems are also known as chirping binaries (Schutz 1986). Laser interferometers can provide crude estimates of the position of the gravitational wave source in the sky. If a source has an observable optical counterpart, the position of the siren could be pinpointed and the distance measurement significantly improved (Schutz 1986).

Accurate redshifts of electromagnetic standard candles are usually easier to obtain than accurate distance measurements. For gravitational wave standard sirens the situation is reversed: accurate distances, but no redshifts, can be obtained. An electromagnetic counterpart could thus not only increase the accuracy in the distance measurable by LISA to $< 1\%$ (Holz & Hughes 2005) but also provides the redshift. Detection of gravitational wave sources with electromagnetic counterparts thus have the potential to probe the distance–redshift relation with unprecedented precision (Schutz 1986). For a recent discussion on possible observable electromagnetic counterparts of massive black hole binaries, see Dotti et al. (2006) and references therein.

The coalescence of supermassive black holes is associated with mergers of proto-galaxies or galaxies, many of which are expected to occur at high redshift. Chirping supermassive binary black holes thus promise to be probes of the very distant Universe. The exact redshift distribution of supermassive binary black holes is, however, poorly known and the estimated number of events detectable by LISA range from a few to hundreds of thousands per year (Menou et al. 2001; Haehnelt 2003; Wyithe & Loeb 2003; Enoki et al. 2004; Islam et al. 2004; Sesana et al. 2004; Rhoads & Wyithe 2005; Sesana et al. 2005; Koushiappas & Zentner 2006). While cosmological parameters can be derived from a Hubble diagram of “standard sirens” at high z , severe parameter degeneracies result unless there are also data points at low redshifts. Since the distances which could be obtained from chirping supermassive black hole binaries are absolute, they could be combined with absolute distances measured using other low redshift probes, e.g. chirping neutron star binaries (Dalal et al. 2006). At high redshifts, distance measurements will be affected by gravitational deflection of the radiation by foreground matter (Markovic 1993). An additional scatter of a factor ~ 10 is thus expected due to gravitational lensing (see Section 4).

In principle, due to flux conservation, the effects of gravitational lensing are expected to average out if a large number of standard candles or sirens are observed. However,

²<http://lisa.jpl.nasa.gov/>

the large uncertainty in the rate, coupled with the fact that it might be difficult to find and observe electromagnetic counterparts, suggests that a scenario where only a handful of standard sirens with redshifts can be measured by LISA is not unlikely. The scatter due to gravitational lensing will then limit the usefulness of the data severely.

In this paper, we propose a method to compensate for the degradation due to lensing, at least partially. Gunnarsson et al. (2006) showed that properties of foreground galaxies can be used to estimate the magnification accurately enough for corrections of individual sources to be useful. The error box in the sky provided by LISA, will probably be extensively observed in many different wavelength bands in the search for an electromagnetic counterpart. This data could be used to estimate the magnification of the siren due to gravitational lensing by foreground matter. For reasonable detection rates of chirping supermassive binary black holes, we show that correcting for gravitational lensing will be comparable to increasing the sample size by a factor three. The corrections will thus be crucial when using the data to constrain cosmological parameters such as the Hubble constant, the matter density and dark energy properties. The cosmology used throughout this paper is the concordance flat Λ CDM model, $[h, \Omega_M, w_0] = [0.7, 0.3, -1]$.

2. CORRECTING GRAVITATIONALLY LENSED SOURCES

In this section we describe how standard sirens can be corrected for gravitational lensing.

2.1. Computing Corrections

As noted, gravitational waves emitted from high redshift standard sirens might be gravitationally deflected by matter along the line of sight. The magnification factor, μ , describes the amplification ($\mu > 1$) or de-amplification ($\mu < 1$) of a source due to gravitational lensing as compared to a universe with homogeneously distributed matter. If D_L is the luminosity distance in a homogeneous universe (which is what is used when estimating cosmological parameters), the observed luminosity distance, D_L^{obs} , affected by gravitational lensing, is $\mu^{-1/2} D_L$.

Gunnarsson et al. (2006) showed that observed properties (e.g. position, spectroscopic or photometric redshift, and luminosity) of intervening galaxies along the line-of-sight of the source can be used to estimate the magnification factor with sufficient accuracy for corrections to be useful. The magnification factor can be computed using halo profiles depending on the mass of the galaxy halo, which can be obtained from the galaxy luminosity

using Tully–Fisher and Faber–Jackson relations. This method has been successfully applied to, e.g. 33 supernovae in the GOODS fields (Jönsson et al. 2006). The luminosity distance corrected for gravitational lensing using the estimated magnification factor, μ_{est} , is

$$D_{\text{L}}^{\text{corr}} = \mu_{\text{est}}^{1/2} D_{\text{L}}^{\text{obs}} = (\mu/\mu_{\text{est}})^{-1/2} D_{\text{L}}. \quad (1)$$

Whether the corrected distance is closer to the D_{L} obtained in a homogeneous universe than the observed distance depends on how close the quantity μ/μ_{est} is to unity, i.e. how well we can estimate the magnifications. This in turn depends on the completeness and accuracy of the foreground galaxy information. We have used the method presented in Gunnarsson et al. (2006) to obtain the precision to which μ_{est} can be estimated for sources out to $z = 4$. The distribution of μ/μ_{est} at a specific redshift was found by computing μ and μ_{est} for a large number of simulated lines-of-sight. Galaxies along each line-of-sight were simulated and the magnification computed using a fiducial model. This value was taken as the true magnification μ . Since the mean of a simulated probability distribution function (PDF) of μ is not exactly unity, each PDF of μ was normalized to ensure a mean of unity. A value of the magnification representing μ_{est} was also computed assuming a limiting galaxy magnitude and a reasonable error budget including the effects of using the wrong lens model (for 50% of the lenses a SIS-profile was used instead of a NFW-profile) and uncertainties in redshifts and positions as well as intrinsic scatter and accuracy in the Tully–Fisher and Faber–Jackson relations. Since new powerful instruments for electromagnetic observations should be available when LISA can be expected to be operational, our simulations assume galaxy optical limiting magnitude of $I = 28$. In these simulations we have only considered the gravitational deflection due to galaxies and neglected any effects of large scale structures.

2.2. Distance Probability Distribution Functions

The accuracy to which the luminosity distance to chirping supermassive binary black holes could be measured by LISA, neglecting the effects from lensing, has been investigated by Holz & Hughes (2005). In their most optimistic scenario, where an electromagnetic counterpart was assumed, the fractional error in the distance measured for sirens at redshift $z = 1$ and $z = 3$ was found to be $\delta D_{\text{L}}/D_{\text{L}} \sim 0.1\%$ and $\delta D_{\text{L}}/D_{\text{L}} \sim 0.5\%$, respectively. We use these numbers and linear interpolation and extrapolation to obtain the fractional errors used in subsequent calculations. The PDF describing the dispersion in the distance obtained from an unlensed standard siren is assumed to be a Gaussian.

Supermassive binary black holes thus have the potential to be almost perfect (absolute) standard sirens and the gain from being able to minimize any additional scatter, e.g. lensing, can be very large.

The PDF of the observed luminosity distance $D_L^{\text{obs}} = \mu^{-1/2} D_L$ is given by the convolution of the PDFs of $\mu^{-1/2}$ and D_L . Both PDFs depend on redshift and, to some extent, on cosmological parameters. Corrected luminosity distances are expected to be distributed according to the PDF given by the convolution of the PDFs of $(\mu/\mu_{\text{est}})^{-1/2}$ and D_L . The cosmology dependence on the magnification factor is weak and is therefore neglected.

Figure 1 shows the PDFs of luminosity distances measured from unlensed, lensed, and corrected standard sirens at different redshifts. Solid lines indicate the luminosity distance PDF for unlensed sirens. Gravitational lensing introduces asymmetry and additional dispersion to the observed luminosity distance PDF as can be seen from the dotted curves. If the observed distances are corrected for gravitational lensing, both dispersion and asymmetry can be significantly reduced. Corrected PDFs are indicated by dashed lines.

Although the mean magnification factor is unity, the mean of $\mu^{-1/2}$ might be different from unity depending on the moments of the PDF of μ . The mean luminosity distance of a lensed or corrected standard siren might thus be biased compared to an unlensed siren. This bias can be circumvented if D_L^{-2} is considered instead of D_L (see Section 4). For a lensed standard siren at $z = 1$ the mean luminosity distance is overestimated by $\sim 0.1\%$ and this effect increases with redshift to $\sim 0.6\%$ at $z = 4$. Correcting for gravitational lensing reduces the bias at $z \lesssim 3$, but increases the bias at $z = 4$ where the mean of the corrected luminosity distance is overestimated by $\sim 1\%$. However, since we expect only one or a few standard sirens at each redshift, the location of the mode is more important than the mean. As can be seen in Figure 1, the mode of the corrected luminosity distance PDF is always closer to the true unlensed distance than the mode of the observed (lensed) luminosity distance.

After correcting for gravitational lensing, we are left with an absolute standard siren with an almost Gaussian dispersion of $\delta D_L/D_L \sim 1\%$ and $\delta D_L/D_L \sim 3\%$ at redshift $z = 1$ and $z = 4$, respectively.

2.3. Distance Error from Position Uncertainty

The accuracy to which the position of the standard siren could be determined affects not only the distance determination, but also the uncertainty of the estimation of the magnification factor. If the position of the siren could be narrowed down to the host galaxy only, the dispersion in the corrected luminosity distance could be significantly increased. An uncertainty of 3 arcseconds in the position of the source increases the dispersion in the corrected luminosity distance with 10% and 60% at redshift $z = 1$ and $z = 4$, respectively. In the following, we assume that the position of the source is pinpointed with enough precision

for this source of error not to dominate. Note, however, that this corresponds to arcsecond resolution at $z = 4$ which could be an optimistic assumption.

2.4. Groups, Clusters, and Dark Halos

In the previous sections, we have assumed a one-to-one relation between luminous galaxies and dark matter halos. If this assumption is relaxed, our ability to predict lensing magnifications could potentially be severely impaired. This could be caused by, e.g. completely dark halos without any galaxies, and dark matter halos hosting groups or clusters of galaxies. We have investigated the size of this effect by simulating lines-of-sight using publicly available halo and galaxy catalogs constructed from the results of N-body simulations (Kauffmann et al. 1999). Particles in the simulations which were not bound to any halo were treated as if they belonged to a smooth matter component (see Gunnarsson et al. (2006) for details). To compute the true magnification factors, data from the halo catalogs, including halo masses, were used. When the magnification factor was estimated, data from the galaxy catalogs were used and halo masses were obtained from galaxy luminosities following the prescription in Gunnarsson et al. (2006). However, we used a different Tully–Fisher relation (Giovanelli et al. 1997) in order to match the normalization of the models used by Kauffmann et al. (1999). In the calculations of the magnification factors all halos were parametrized as truncated NFW-profiles.

We have studied the effects of groups, clusters, and dark halos on our ability to predict the magnification of a source at $z = 1.5$. For a source at this redshift the dispersion, in terms of the root mean square deviation, of the PDF of μ is $\sim 7\%$ and the corresponding dispersion in the luminosity distance PDF is $\sim 3\%$. If the magnification could be recovered exactly, the dispersion in μ/μ_{est} would vanish.

The effect of dark halos is partly taken into consideration in Gunnarsson et al. (2006) where galaxies fainter than the magnitude limit play the role of completely dark halos. However, to make an extremely conservative estimate, we use simulated lines-of-sight from N-body results where only the most massive, but not all, of the halos contain galaxies (Kauffmann et al. 1999). The contribution to the dispersion in μ/μ_{est} due to the $\sim 90\%$ of the halos in the simulated lines-of-sight which are not associated to any galaxy and thus cannot be modelled, is $\sim 3\%$.

Approximately 2% of the dark matter halos host more than one galaxy, corresponding to groups or clusters of galaxies. Even though this number is low, since these halos are also the most massive ones, the effect of poor modelling of groups of galaxies could potentially add a

sizeable dispersion. Our simulations show that these halos add a dispersion of $\sim 3\%$ to the dispersion of μ/μ_{est} . However, since groups and clusters of galaxies could be identified, better modelling of the halos of these systems might be used, which would reduce the dispersion. For lines-of-sights in the outskirts of clusters even lensing maps constructed from multiple image systems might be used to estimate the magnification.

If a $\sim 50\%$ scatter in the relation between galaxy luminosity and mass, completely dark halos, and poor modelling of galaxy groups are taken into account, the dispersion in the magnification factor can be reduced from $\sim 7\%$ to $\sim 4\%$. This translates into an improvement in the dispersion in the luminosity distance from $\sim 3\%$ to $\sim 2\%$. Such a reduction of the dispersion corresponds to increasing the sample size by almost a factor 3. However, the mean of the corrected luminosity distance is underestimated by $\sim 1\%$, considerably worse than the bias of $\sim 0.2\%$ toward higher mean in the case of observed (lensed) luminosity distance.

A biased relation between galaxy luminosity and halo mass could severely impair our capability to correct for gravitational lensing. If all masses were underestimated by $\sim 50\%$, the dispersion in the magnification factor and luminosity distance could be reduced to $\sim 5\%$ and $\sim 2\%$, respectively. Since the the mean of the corrected luminosity distance is underestimated by only $\sim 0.5\%$ in this case, such a bias in the luminosity-mass relation would not significantly hamper or ability to correct for lensing.

If, on the other hand, all masses were overestimated by $\sim 50\%$, correcting for gravitational lensing would instead increase the dispersion in μ/μ_{est} to $\sim 10\%$, ruining our attempt to correct for gravitational lensing. Since we require the total mass in halos to be $\leq \Omega_{\text{M}}$, a too large bias toward higher halo masses would be discovered. Furthermore, any substantial bias in the luminosity-mass relation should give worse residuals in the Hubble diagram after correcting data for lensing than before.

In the so called realistic scenario outlined in Gunnarsson et al. (2006), where several effects are taken into account, the dispersion in μ/μ_{est} for a source at $z = 1.5$ is $\sim 3\%$. The discussion above lead us to the conclusion that in order for lensing corrections to be useful, the dispersion in μ/μ_{est} must be $\lesssim 5\%$, leaving us with an error budget of $\sim 4\%$ for dark halos and groups and clusters of galaxies. Since our extremely conservative analysis yields $\lesssim 4\%$, we are confident that this number is within reach.

3. IMPROVING COSMOLOGICAL PARAMETER ESTIMATION

To illustrate the improvement if corrections for gravitational lensing are applied, we have fitted cosmological parameters to simulated data sets and plotted the corresponding confidence contours.

3.1. Simulated Data Sets

Our fiducial supermassive binary black hole data set consists of 10 luminosity distance measurements to standard sirens evenly distributed in the redshift range $1 \leq z \leq 4$ with errors as described in Section 2.2 (high redshift sample). In addition, chirping neutron star binaries might provide gravitational wave standard sirens with optical counterparts at low redshifts (Dalal et al. 2006). We assume 5 additional distance measurements at low redshifts, $0.04 \leq z \leq 0.12$ (low redshift sample). The fractional error in these distances were assumed to be given by $\delta D_L/D_L = D_L^2/(1700 \text{ Gpc})$ adopted from Dalal et al. (2006). Since the improvement from correcting for lensing corresponds to a factor of three in sample size almost independently of the exact rate and redshift distribution of standard sirens (see Section 4), the fractional improvement in the confidence contours can be appreciated although the absolute number of well observed sirens is highly uncertain.

3.2. Maximum Likelihood Technique

Since the PDFs of lensed distances are expected to be asymmetric (see Figure 1), a maximum likelihood technique is used to fit cosmological parameters to the simulated data. Given a data set of redshifts and luminosity distances, $\{z_i, D_i\}$, obtained from gravitational wave standard sirens and their electromagnetic counterparts, cosmological parameters can be estimated by maximizing the logarithm of the likelihood,

$$\log L(\theta) = \sum_i \log f(D_i; z_i, \theta), \quad (2)$$

where θ represents the cosmological parameters whose values we want to estimate. We fit parameters to data sets consisting of unlensed ($D = D_L$), lensed ($D = \mu^{-1/2} D_L$), and corrected ($D = (\mu/\mu_{\text{est}})^{-1/2} D_L$) luminosity distances. For each data set the corresponding PDF, $f(D; z, \theta)$, is used. Since the effects of gravitational lensing are redshift dependent, PDFs for lensed and unlensed luminosity distances are redshift dependent too. Low redshift sirens, with negligible magnification due to lensing, are assumed to be described by a Gaussian PDF.

In the cosmology fits, a model for luminosity distances in a flat universe is used,

$$D_L(z; h, \Omega_M, w_0, w_a) = (1+z) \int_0^z \frac{dz'}{H(z')}. \quad (3)$$

This model depends on the Hubble constant, $H_0 = 100h \text{ km s}^{-1} \text{ Mpc}^{-1}$, the matter density, Ω_M , and the equation of state parameter of dark energy parametrized by (e.g. Linder 2003) $w(z) = w_0 + w_a z/(1+z)$, via the Hubble parameter,

$$H^2(z) = H_0^2 [\Omega_M(1+z)^3 + (1-\Omega_M)(1+z)^{3(1+w_0+w_a)} e^{-3w_a z/(1+z)}]. \quad (4)$$

Note that chirping binaries, in contrast to e.g. Type Ia supernovae, are absolute distance indicators, i.e. we don't have to marginalize over any non-cosmological parameters. We have considered the effects on confidence level contours for both constant and time varying dark energy equation of state parameters. In the cases where the equation of state parameter was assumed to be constant, the parameter w_a was put to zero and one of the three remaining parameters was either marginalized over or assumed to be exactly known. When a time varying equation of state parameter was considered, prior information on Ω_M and h was used.

3.3. Effects on Cosmology Fits

Figure 2 shows the results of the cosmology fits where a constant equation of state parameter was assumed, i.e. $w_a = 0$. Each panel in the figure shows 68.3% confidence level contours ($\log L(\theta) = \log L_{\max} - 2.30/2$) for unlensed (solid contours), lensed (dotted contours), and corrected (dashed contours) data sets. Each column of panels in the figure shows the results of cosmological parameters fitted to different data sets. The left column shows results obtained for the high redshift sample. The middle column shows the effect of adding the low redshift sample. The right column of panels shows the results of cosmology fits where the third parameter was assumed to be exactly known. This gives an indication of the dependence of the size of the contours on the marginalization over and prior knowledge of the third parameter.

Panel a shows confidence level contours in the $[\Omega_M, w_0]$ -plane obtained for a simulated data set consisting of 10 high redshift standard sirens. Gravitational lensing degrades the data set and the cosmological results that can be obtained from it. However, the size of the confidence level contours can be significantly reduced if the data are corrected for lensing magnification. Distance measurements at low redshifts are much more useful in constraining h than distance measurements at high redshifts. Adding low redshift distance measurements

to the high redshift data set thus have effects similar to applying prior information on h . Panel b shows the improvement on the confidence level contours due to 5 additional distance measurements at low redshifts. Panel c shows the very tight constraints in the $[\Omega_M, w_0]$ -plane which could be obtained if h was exactly known.

The middle row of panels shows results similar to those presented in the top row of panels, but in the $[h, \Omega_M]$ -plane. Panel d shows the contours obtainable from 10 high redshift standard sirens. The improvement due to 5 additional low redshift standard sirens can be seen in panel e. A data set consisting of both high and low redshift distances could potentially give constraints on Ω_M and h on the 10% level. Panel f shows the results for the case where w_0 is assumed to be exactly known. Note that assuming that the dark energy is accurately described by a cosmological constant, as current data favors (e.g. Hannestad & Mörtsell 2004), standard sirens have the potential to give very strong constraints on the Hubble parameter, h , if we correct for gravitational lensing.

The bottom row of panels show results in the $[h, w_0]$ -plane. Panel g shows confidence level contours obtained from 10 high redshift sirens. The improvement due to 5 additional low redshift standard sirens can be seen in panel h. Panel i shows the results for the case where Ω_M is assumed to be exactly known.

Results obtained from the high redshift data sets of lensed or corrected sirens suffer from severe degeneracies. The (one-sided) limits on Ω_M , w_0 and h which could be obtained from the high redshift sample alone, without any priors or low redshift distance measurements, would not be competitive compared to other measurements of these parameters. Priors or low redshift data seem to be necessary for a small set of high redshift standard sirens to be able to give competitive constraints on Ω_M , w_0 and h .

Figure 3 shows the results in the $[w_0, w_a]$ -plane. Solid, dotted, and dashed lines indicate the 68.3% confidence level contours obtained for unlensed, lensed, and corrected data sets. Gaussian priors, assuming h and Ω_M to be known with 3% accuracy, were used in the fitting procedure. Panel a shows the contours obtained from the high redshift data set. The effect of adding the low redshift data set is small and is shown in panel b. Since strong priors have already been applied, there is no dramatic improvement due to broken degeneracies. Panel c shows the contours obtained with both h and Ω_M exactly known. The set of 10 high redshift sirens is evidently not sufficient to yield very strong constraints on w_0 and w_a even in the case where the Hubble constant and the matter density are exactly known. Larger data sets than the ones considered here are thus needed for standard sirens to be able to provide very strong constraints on the evolution of dark energy.

In Table 1 and 2 the numerical results are summarized. The 68.3% confidence level

intervals in the tables were obtained by finding the extremal values of the cosmological parameter θ (where θ is h , Ω_M , w_0 , or w_a) fulfilling the condition $\log L(\theta) = \log L_{\max} - 2.30/2$.

4. FLUX AVERAGING

For a large number of sources, all at the same redshift, the mean magnification is expected to be unity due to flux conservation. Since gravitational wave flux is inversely proportional to the luminosity distance squared, the mean of $D_{L,\text{obs}}^{-2} = \mu D_L^{-2}$ equals D_L^{-2} . The mean of the observed luminosity distance is, on the other hand, expected to be biased by 0.1% – 0.6% as noted in Section 2.2. This bias is similar to the one which arises if magnitudes are used instead of fluxes. However, whether this bias is important or can be ignored depends on the sample size and the errors in each distance measurement. In the scenario studied in this paper, where the standard sirens are sparsely distributed in redshift, the position of the mode is more important than the mean and we can use D_L^{obs} instead of $D_{L,\text{obs}}^{-2}$ as our observable.

Degradation by gravitational lensing can thus be cured by studying the mean of the luminosity distance (or inverse of the luminosity distance squared if it is important to avoid a biased mean) $\bar{D}_L$ with uncertainty $\sigma_{\bar{D}_L}$, if the number of sources is large enough (Holz & Linder 2005). We now estimate how large this number of supermassive binary black holes is.

Figure 4 shows the dispersion of the luminosity distance PDFs as a function of redshift, quantified in terms of the root mean square of the deviation from the mean, σ_{D_L} . The increase in the dispersion, due to lensing, depends on the redshift. At $z = 1$ and $z = 4$ the dispersion is increased a factor ~ 20 and ~ 10 , respectively. If the distances obtained from the sirens are corrected, the dispersion can be reduced by a factor ~ 2 . If a number of lensed sirens, all at the same redshift, would be observed, how many would be needed to compensate for the dispersion due to lensing? The dispersion of the mean value of the distances inferred from the standard sirens should be inversely proportional to the square root of the number of sirens,

$$\sigma_{\bar{D}_L} = \sigma_{D_L}^{\text{lensed}} N^{-1/2} \quad (5)$$

To restore the dispersion to the value corresponding to one unlensed siren, i.e. $\sigma_{\bar{D}_L} = \sigma_{D_L}^{\text{unlensed}}$, the needed number of observed sirens would thus be,

$$N = (\sigma_{D_L}^{\text{lensed}} / \sigma_{D_L}^{\text{unlensed}})^2. \quad (6)$$

Since the dispersion of an unlensed siren increases much faster as a function of redshift than the dispersion of a lensed or corrected siren, the number of sirens needed to compensate for lensing is much larger at $z = 1$ ($N \sim 500$) than $z = 4$ ($N \sim 70$). Only in very optimistic

scenarios would we be able to observe such a large number of sources including optical counterparts.

The number of lensed sirens needed to achieve a dispersion comparable to the dispersion of one corrected siren is

$$N = (\sigma_{D_L}^{\text{lensed}} / \sigma_{D_L}^{\text{corrected}})^2 \sim 3, \quad (7)$$

almost independent of redshift. Thus, unless the number of well-observed sirens is very large, by correcting for the effects of gravitational lensing, we are able to improve our data by an amount that is comparable to increasing the sample size by a factor of three.

5. SUMMARY AND DISCUSSION

Gravitational waves emitted by chirping supermassive black hole binaries measured by LISA could in principle provide very accurate distance determinations. If electromagnetic counterparts of these events could be found, from which redshifts could be determined, these standard sirens could be used to build a high redshift Hubble diagram. In principle, chirping binaries are almost perfect distance indicators, only limited by the precision of the position measurement. Thus, the need of controlling systematic errors on the distance measure is crucial to be able to use the standard sirens to their full potential. These errors will most likely be completely dominated by gravitational lensing.

Since the number of expected events is uncertain and whether optical counterparts exist or can be observed is even more unclear, we have reasons to believe that the number of events which could be put in a Hubble diagram is low. Thus, we can not be certain that the degradation due to gravitational lensing can be overcome by large statistics. From Figure 2 and 3, it is obvious that correcting for gravitational lensing can be crucial for the competitive use of gravitational wave standard sirens in cosmology. Note also that the actual number of observed sirens with electromagnetic counterparts at very high redshift ($z > 4$) might be substantial (Dotti et al. 2006), in which case the effects from gravitational lensing will be even larger.

Low redshift points in the Hubble diagram (where the luminosity distance mainly is sensitive to the Hubble constant) are important to break some of the degeneracies on the cosmological parameters occurring for high redshift luminosity distances, but no supermassive black hole binaries are expected at low redshift. The situation is thus very similar to the case of using gamma ray bursts as standard candles where, apart from the difficulty of calibrating the candles, the lack of low redshift sources weakens their power to constrain cosmological parameters, see Mörtzell & Sollerman (2005). Since chirping supermassive black

hole binaries are absolute standard candles however, their usefulness for cosmology could be increased if they are combined with other absolute distance determinations in the local universe.

Besides constraining the distance–redshift relation, standard sirens have other potential applications in cosmology. Since the dispersion from gravitational lensing depends on the matter distribution in the universe, it could in principle be used to constrain cosmological parameters. Equivalent to the use of galaxy shear measurements, the lensing magnification PDF can provide information on σ_8 and Ω_M . The feasibility of the method has been studied in the context of future Type Ia supernova observations in Cooray et al. (2006) and Dodelson & Vallinotto (2005). In this paper, we only note that standard sirens have the potential to be even better probes of the cosmic magnification, due to the much smaller (at least a factor of ten) intrinsic scatter in the luminosity (Cooray et al. 2006). Also, the large distances to the standard siren sources makes it possible to study the matter distribution in the universe at high redshifts. However, whether this potential can be realized depends upon the very uncertain detectability rate and the possibility to secure redshifts for the sources.

Even if the number of observed sirens turns out to be low, the small intrinsic dispersion combined with the fact that chirping binaries are absolute standard candles allows us to measure the magnification for individual sources and thus probe the matter content, i.e., the convergence κ along individual lines-of-sight. This could yield important information on the matter distribution in clusters and galaxies. Specifically, it could be used to break the mass sheet degeneracy that plagues galaxy shear investigations.

In conclusion, we note that although detection rates are very uncertain, LISA could in principle provide high precision distance measurements to very distant objects in the Universe, the error of which will be dominated by gravitational lensing. Correcting for these errors is comparable to increasing the sample size by a factor of three which decreases the error contours for cosmological parameters substantially. Depending on the exact redshift distribution of the sirens, this could yield competitive constraints on, in particular, the Hubble constant and the matter density, but perhaps also on dark energy properties.

The authors would like to thank Tomas Dahlén and Christofer Gunnarsson for help with the gravitational lensing simulations and an anonymous referee for constructive criticism. AG would like to acknowledge support by the Swedish Research Council and the Göran Gustafsson Foundation for Research in Natural Sciences and Medicine.

Fig. 1.— Probability distribution functions (PDF) for luminosity distances obtainable from unlensed, lensed, and corrected standard sirens at different redshifts. The fractional uncertainty to which the luminosity distance to an unlensed siren could be measured by LISA is indicated in each panel.

Fig. 2.— Confidence level contours at the 68.3% confidence level for different cosmological parameters and different simulated data sets. Solid, dotted, and dashed contours corresponds to unlensed, lensed, and corrected data sets, respectively. Panel a: High redshift data set. Panel b: High and low redshift data sets. Panel c: High redshift data set but h is known exactly. Panel d: High redshift data set. Panel e: High and low redshift data sets. Panel f: High redshift data set but w_0 is known exactly. Panel g: High redshift data set. Panel h: High and low redshift data sets. Panel i: High redshift data set but Ω_M is known exactly. Note the different scales in the figures.

Fig. 3.— Confidence level contours at the 68.3% confidence level in the $[w_0, w_a]$ -plane for different data sets. Solid, dotted, and dashed contours corresponds to unlensed, lensed, and corrected data sets, respectively. Panel a: High redshift data set. Panel b: High and low redshift data sets. Panel c: High redshift data set but h and Ω_M are known exactly. Gaussian priors (3% accuracy) on h and Ω_M were used in the fitting procedure.

Fig. 4.— Root mean square deviation of the probability distribution functions of unlensed, lensed, and corrected standard sirens as a function of redshift.

Table 1. A summary of the results of the cosmology fits shown in Figure 2. Quoted 68.3% confidence level intervals for Ω_M , w_0 , and h were obtained by finding the extremal value of the cosmological parameter θ where $\log L(\theta) = \log L_{\max} - 2.30/2$.

Simulated Data Set		Ω_M	w_0	h
High-z	Unlensed	[0.25, 0.32]	[−1.6, −0.7]	[0.64, 0.82]
	Lensed	< 0.40	< −0.2	> 0.57
	Corrected	< 0.34	< −0.4	> 0.61
High-z + low-z	Unlensed	[0.28, 0.31]	[−1.2, −0.8]	[0.67, 0.75]
	Lensed	[0.20, 0.38]	[−1.6, −0.5]	[0.63, 0.80]
	Corrected	[0.26, 0.34]	[−1.5, −0.6]	[0.64, 0.78]
High-z + h known	Unlensed	[0.29, 0.31]	[−1.02, −0.98]	...
	Lensed	[0.25, 0.35]	[−1.27, −0.83]	...
	Corrected	[0.28, 0.33]	[−1.14, −0.94]	...
High-z + Ω_M known	Unlensed	...	[−1.12, −0.79]	[0.67, 0.72]
	Lensed	...	[−1.67, −0.38]	[0.59, 0.77]
	Corrected	...	[−1.34, −0.56]	[0.63, 0.74]
High-z + w_0 known	Unlensed	[0.29, 0.31]	...	[0.696, 0.704]
	Lensed	[0.25, 0.37]	...	[0.66, 0.73]
	Corrected	[0.28, 0.34]	...	[0.68, 0.71]

Table 2. A summary of the results of the cosmology fits shown in Figure 3. Quoted 68.3% confidence level intervals for w_0 and w_a were obtained by finding the extremal value of the cosmological parameter θ where $\log L(\theta) = \log L_{\max} - 2.30/2$.

Simulated Data Set		w_0	w_a
High-z	Unlensed	$[-1.13, -0.85]$	$[-0.6, 0.4]$
	Lensed	$[-1.41, -0.44]$	$[-3.8, 1.5]$
	Corrected	$[-1.29, -0.83]$	$[-1.6, 0.9]$
High-z + low-z	Unlensed	$[-1.13, -0.86]$	$[-0.6, 0.4]$
	Lensed	$[-1.40, -0.59]$	$[-2.8, 1.5]$
	Corrected	$[-1.25, -0.83]$	$[-1.4, 0.9]$
High-z + h and Ω_M known	Unlensed	$[-1.04, -0.96]$	$[-0.2, 0.2]$
	Lensed	$[-1.36, -0.69]$	$[-1.6, 1.6]$
	Corrected	$[-1.19, -0.86]$	$[-0.8, 0.8]$

Note. — In the fitting procedure Gaussian priors (3% accuracy) on h and Ω_M were used.
